## 1 Abstract

In this report, we will introduce how to use logistic regression and softmax regression to do handwritten digits classification. We did extensive experiments on the MNIST datasets. For 2-way classification, we can achieve an accuracy of 98% if the targets are digit '2' and digit '3' and we can achieve an accuracy of 97% if the targets are digit '2' and digit '8' by using logistic regression. For 10-way classification, we can achieve an accuracy of 93.65% by using softmax regression.

## 2 Logistic Regression via Gradient Descent

### 2.1 Problem Definition

In this work, we realize the handwritten digit classification using MNIST database. Our goal is to accurately and robustly recognize what number is present in a new image. In this section we will first use logistic regression to classify only two digit classes (binary classification), later in the next section we will use softmax regression to generalize logistic regression into  $N$  classes.

### 2.2 Mathematical Derivation of Gradient

**Derive the gradient for logistic regression:**

The cross-entropy cost function can be expressed as

$$E(w) = - \sum_{n=1}^N [t^n \ln(y^n) + (1 - t^n) \ln(1 - y^n)] \quad (1)$$

where  $t^n$  is the target label for example  $n$  and  $y^n$  is our prediction for this example. To perform gradient descent, we need to first compute the gradient (derivative) of the cost function with respect to the parameters. The gradient of cost function on example  $n$  is

$$-\frac{\partial E^n(w)}{\partial w_j} = \frac{\partial [t^n \ln(y^n) + (1 - t^n) \ln(1 - y^n)]}{\partial w_j} \quad (2)$$

where  $y^n$  is the prediction of logistic regression as

$$y^n = g\left(\sum_{j=0}^m w_j x_j^n\right) \quad (3)$$

(a) cost function with iterations for batch GD on classifying 2 vs. 3

(b) cost function with iterations for batch GD on classifying 2 vs. 8

Figure 1: Cost function through batch GD training process

and  $g(\cdot)$  is the sigmoid activation function and its derivative is

$$g'(z^n) = \frac{d(\frac{1}{1+e^{-z^n}})}{dz^n} = g(z^n)(1 - g(z^n)) \quad (4)$$

where  $z^n = \sum_{j=0}^m w_j x_j^n$ . According to the chain rule in calculus, we can then compute the gradient (derivative) of the cost function on example  $n$  with respect to the parameters as

$$-\frac{\partial E^n(w)}{\partial w_j} = -\frac{\partial E^n(w)}{\partial y^n} \frac{\partial y^n}{\partial z^n} \frac{\partial z^n}{\partial w_j} = (\frac{t^n}{y^n} - \frac{1-t^n}{1-y^n}) \cdot y^n(1-y^n) \cdot x_j^n = (t^n - y^n)x_j^n \quad (5)$$

Note that we can always add a factor of  $1/N$  to scale the cost and gradient to somehow speed up the learning, and this will not change the optimization results (learned parameters).

### 2.3 Data Reading, Parsing and Feature Extraction

In this work we use the famous MNIST hand written digits database created by Yann LeCun. Each image in the database contains  $28 \times 28$  pixels and each pixel has a grayscale intensity, so that the input feature  $x \in R^{784}$  after we unroll the 2D image into an 1D vector. To include the bias term, after reading the data, we append a '1' to the beginning of each  $x$  vector so the final  $x \in R^{785}$ . We will use the first 20,000 training images and the last 2,000 test images. Note that for logistic regression to do binary classification, we can only use the images of two specific digit classes, so that the actual training images and test images are smaller than 20,000 and 2,000 respectively. To speed up learning, we need to apply feature normalization. For images, the most common way is to normalize the pixel values by the maximum pixel value 255. After normalization, all the values in  $x$  is now ranging from 0 to 1.

The following code shows how we can choose the example images corresponding to two specific digit classes. For the rest of the report, we choose two binary classification problems: 2 vs. 3 and 2 vs. 8.

*TODO: Attach code here.*

### 2.4 Experimental Results

#### Batch gradient descent

We first apply batch gradient descent rule on logistic regression since the training set is not that huge, thus batch gradient descent can work reasonably fast.

(a) cost function with iterations for mini-batch GD on classifying 2 vs. 3

(b) cost function with iterations for mini-batch GD on classifying 2 vs. 8

Figure 2: Cost function through mini-batch GD training process

(a) accuracy with iterations on classifying 2 vs. 3

(b) accuracy with iterations on classifying 2 vs. 8

Figure 3: Accuracy through training process

After trying different values of learning rate, we found 0.005 is a reasonably good learning rate for this problem. Fig. ??(a) plots the loss function over training for the training set, the hold-out validation set and the test set. From the results we can see the model tries to minimize the cost and meanwhile maximize the likelihood to perform good prediction on the data.

### Mini-Batch gradient descent

We can use mini-batch gradient descent to speed up learning process. Since the one-step optimization is done on a smaller mini-batch, the cost function will not monotonically decrease as batch gradient descent. Here we change the weights after a mini-batch of roughly 10% of the entire training set. This set of mini-batch size can result in relatively smooth curve of the cost function. Fig. ??(b) plots the loss function over training for consecutive mini-batches. Since the validation set always has very similar errors as the test set, we can conclude the hold-out set work as a good stand-in for the test set and their underlying data distributions are same.

### Accuracy of Prediction Using Logistic Regression Classifier

#### Weight Visualization

We can visualize the weights learned to see what logistic regression learns through the training process.

Computing the difference between these two different classifiers, we can get a new weight matrix visualized in Fig. ?. This result shows that the new weights can be used to accurately classify digit 3 and digit 8.

Figure 4: Weight visualization on binary classification using logistic regression

Figure 5: Difference of the weights between the two classifiers (2 vs. 3 and 2 vs. 8)

In the next part of this section, we are going to add regularization to our model and analyze it via experiments.

## 2.5 Derive the gradient for regularized logistic regression:

To prevent potential overfitting, regularization is used in logistic regression. The cross-entropy cost function with regularization term can be computed as

$$E(w) = - \sum_{n=1}^N [t^n \ln(y^n) + (1 - t^n) \ln(1 - y^n)] + \lambda * C(w) \quad (6)$$

where  $C(w)$  represents the complexity of the model.  $L1$  and  $L2$  regularizations are two most common functions people use

$$C(w) = \|w\|^2 = \sum_{i,j} w_{i,j}^2 (L2) \quad (7)$$

Figure 6: accuracy using L1 regularization

Figure 7: accuracy using L2 regularization

$$C(w) = |w| = \sum_{i,j} |w_{i,j}|(L1) \quad (8)$$

Thus the gradient of cost function on example  $n$  is

$$-\frac{\partial E^n(w)}{\partial w_j} = \begin{cases} (t^n - y^n)x_j^n - 2\lambda w_j, & \text{if } L2 \\ (t^n - y^n)x_j^n - \lambda \text{sign}(w_j), & \text{if } L1 \end{cases}$$

where  $\text{sign}(w_j)$  is the signature function of  $w_j$ .

Note that we can always add a factor of  $1/N$  to scale the cost and gradient to somehow speed up the learning, and this will not change the optimization results (learned parameters).

### Tuning the Regularization Parameter

In order to choose a reasonably good regularization model, we need to tune the regularization parameter and choose the one which results in the best accuracy on the hold-out validation set. Here we try three values for regularization parameter  $\lambda$ : 0.0001, 0.001 and 0.01. Fig. 6 and Fig. 7 show the results with different  $\lambda$  on L1 and L2 regularization.

### Reality Check on the Length of Weight Vector

Fig. 8 shows the experimental results using L1 and L2 regularization.

From the figures we can see that stronger regularization will result in smaller weights since the regularization penalizes large weights.

### Final Test Set Error with Regularization

We also plot the final test set error with different values of the regularization parameter.

### Weight Visualization with Regularization

We further visualize the weights learned with our regularized model.

### 3 Softmax Regression via Gradient Descent

#### 3.1 Problem definition

In this problem, we need to classify MNIST datasets using softmax regression. In the experiments, we only use the first 20,000 training images and the last 2,000 test images.

#### 3.2 Methods

##### Derive the gradient for Softmax Regression:

The cross-entropy cost function can be expressed as,

$$E = - \sum_n \sum_{k=1}^c t_k^n \ln y_k^n \quad (9)$$

Where,

$$y_k^n = \frac{\exp(a_k^n)}{\sum_{k'} \exp(a_{k'}^n)} \quad (10)$$

And,

$$a_k^n = w_k^T x^n \quad (11)$$

We can calculate the gradient for softmax regression as follows,

$$\begin{aligned} -\frac{\partial E^n(w)}{\partial w_{jk}} &= -\frac{\partial E^n(w)}{\partial a_k^n} \frac{\partial a_k^n}{\partial w_{jk}} \\ &= -\sum_{k'} \frac{\partial E^n(w)}{\partial y_{k'}^n} \frac{\partial y_{k'}^n}{\partial a_k^n} \frac{\partial a_k^n}{\partial w_{jk}} \end{aligned} \quad (12)$$

And

$$\frac{\partial y_{k'}^n}{\partial a_k^n} = y_{k'}^n \delta_{kk'} - y_{k'} y_k \quad (13)$$

Where  $\delta_{kk} = 1$  if  $k = k'$ , otherwise  $\delta_{kk} = 0$ . And

$$\frac{\partial E^n(w)}{\partial y_{k'}^n} = -\frac{t_{k'}}{y_{k'}} \quad (14)$$

Substitute Equation (5) and Equation (6) into Equation (4) we get,

$$-\frac{\partial E^n(w)}{\partial w_{jk}} = (t_k - y_k) x_j^n \quad (15)$$

### Derive the gradient for Softmax Regression with Regularizations:

With regularization, generally the loss function can be written as,

$$J(w) = E(w) + \lambda C(w) \quad (16)$$

If we use  $L_1$  regularization in softmax regression,

$$\lambda C(w) = \lambda C_{L_1}(w) = \lambda \sum_{ij} |w_{i,j}| \quad (17)$$

We can compute the derivate of  $\frac{\partial C}{\partial w}$  as follows,

$$\frac{\partial C_{L_1}(w)}{\partial w_{ij}} = \text{sign}(w_{i,j}) \quad (18)$$

Where  $\text{sign}(x) = 1$  if  $x > 0$ ,  $\text{sign}(x) = 0$  if  $x = 0$  and  $\text{sign}(x) = -1$  if  $x < 0$ .

If we use  $L_2$  regularization in softmax regression,

$$\lambda C(w) = \lambda C_{L_2}(w) = \lambda \sum_{ij} w_{i,j}^2 \quad (19)$$

We can compute the derivate of  $\frac{\partial C}{\partial w}$  as follows,

$$\frac{\partial C_{L_2}(w)}{\partial w_{ij}} = 2w_{i,j} \quad (20)$$

In summary,

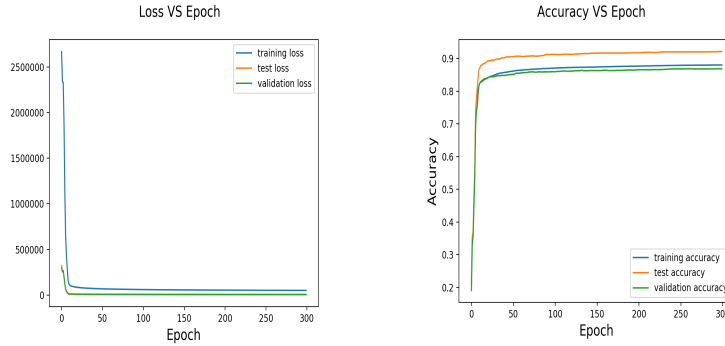

$$-\frac{\partial J^n(w)}{\partial w_{j,k}} = \begin{cases} (t_k - y_k) x_j^n - \lambda \text{sign}(w_{j,k}), & \text{if use } L_1 \text{ regularization} \\ (t_k - y_k) x_j^n - 2\lambda w_{j,k}, & \text{if use } L_2 \text{ regularization} \end{cases}$$

**Preprocessing:** First, we extract the first 20,000 training images and the last 2,000 test images. Then normailize the images to make sure the pixel values are in the range of [0,1]. Convert the labels to one-hot vectors. Divide the training images into two parts, the first 10% are used for as a hold-out set and the rest 90% are used for training.

**Experiments settings:** We use standard normal distributions to initilize the weights. We use an initial learning rate  $\eta(0) = 0.003$  and use equation  $\eta(t) = \eta(0)/(1 + t/T)$  to anneal the learning rate by reducing it over time.  $t$  is used to index the epoch number and  $T$  is a metaparameter which is set to be 2. In the experiements, we find that above learning settings work best.

To determine the best type of regurization and the best  $\lambda$ , we try  $L_2$  regularization and  $L_1$  regularization seperately. For the  $L_2$  regularizartion, we search the best  $\lambda$  in the set  $\{0.01, 0.001, 0.0001\}$ . If the accuracy on the hold-out set decreases for 3 epochs, we stop the algorithm and use the weights with the highest accuracy on the hold-out set as the final answer. For the  $L_1$  regularization, we follow the same steps. We run the 1000 epochs for each setting. Then we compare the results got from these two regularization methods and use the best one as the final result.

(a) The value of the loss function over the number of training iterations for the training, hold-out, and test set.

(b) The percent correct over the number of training iterations for the training, hold-out and test set.

Figure 11: The performance of the algorithm over the number of training iterations.

Figure 12: Images of the weights and the average examples. The images in the first row are the images of the weights. The images in the second row are the images of the average examples.

### 3.3 Results

(a) In the experiments, we find that using  $L_2$  regularization with  $\lambda = 0.01$  obtain the best result on the validation set with an accuracy of 0.9045% on the validation set. The accuracy is 0.927% on the test set under such settings.

To further examine the performance of the algorithm, we try other  $\lambda$ s. We choose  $\lambda$  in the set  $\{0.05, 0.005, 0.0005\}$  and use  $L_2$  regularization. The highest accuracy on the validation set is 0.8965% with  $\lambda = 0.0005$ . And the test accuracy is 0.933% which is slightly higher than when  $\lambda = 0.01$ . So in following experiments, we fix  $\lambda$  to be 0.0005.

(b) In this experiment, we use  $L_2$  regularization with  $\lambda = 0.005$ . The figure is shown in Fig 11a. Note that we use the sum of loss of individual data rather than the average one.

(c) In this experiment, we use  $L_2$  regularization with  $\lambda = 0.005$ . The figure is shown in Fig 11b.

(d) We plot the results in Fig 12.

### 3.4 Discussion

From Fig 11a and Fig 11b and we can see that the accuracy and loss function converges quickly and then becomes smooth. The plausible reason is that the learning rates in the first few epoches maybe a little large but after "annealing", the learning rates are suitable enough to make the algorithm converge.

Setting the learning rate too small initially may let the algorithm too slow to converge or just being stucked. And we also see that there is no overfitting occurs. One possible reason for this is that the impact of the regularization. Another one is that the algorithm correctly learns the pattern underlying the data at hand.

From Fig 12 we can see that the image of the weight and the corresponding image of the average digit is almost the same. The reason is that we classify the images based on the inner product of the pixels with the weights. And the inner product is maximized when the angle between the weight and the image is zero. So we see that the image of the weight and the corresponding image of the average digit is similar.

### **3.5**

## **4 Summary**

In this work, we successfully derived and implemented logistic regression (binary classification) and softmax regression (multi-class classification) for handwritten digit classification problem from scratch and achieved roughly 98% classification accuracy. We also embedded regularization to prevent overfitting so that the model generalized well to the unseen test examples. Through rigorous experiments and analysis, we can systematically tune the hyper-parameters and implement model selection by looking at the error on validation set.
